Abstract

Cucurbita pepo is an economically important plant. However, the fact that there are few high-quality varieties that have limited the development of this plant in *Cucurbita* breeding programs. Aiming to provide genetic improvement and application on breeding of *Cucurbita* breeding programs, the diversity of 64 *C. pepo* accessions was analyzed using morphological and simple sequence repeat (SSR) markers. A total of 45 morphological traits in *C. pepo* accessions presented large morphological characteristic variability, from 6.30% (for flower shape) to 70.84% (for fruit umbilicus diameter), with an average variability of 34.43%, whereas the average diversity index of all traits was 1.25, ranging from 0.2% (for seed width) to 4.8% (for seed thickness). Sixty accessions were discriminated into 2 clusters morphological and molecular markers: cluster I included 5 accessions with hull-less seeds, and cluster II included 59 accessions with shell-covered seeds. Cluster II was divided into 5 sub-clusters with different fruit and leaf shapes based on morphological data, and accessions with similar phenotypic features were grouped together. Cluster II was divided into dwarf and normal sub-clusters using SSR markers and accessions with the same origin and same geographical distribution were clustered together. There were some differences between the relationships morphological markers and SSR markers in this study. Morphological markers and SSR markers among the 64 *C. pepo* are not interchangeable methods but are complementary methods that together ensure the comprehensiveness and accuracy of analytical results.

Key words: *Cucurbita pepo*, SSR marker, Morphological marker, Genetic diversity, Cluster analysis.

Introduction

Cucurbita ($2x = 2n = 40$) is an important cucurbitaceous plant that is widely grown as a commercial crop across the globe. It is known to have high nutritional value and health protective properties; therefore, it has attracted an increased interest in recent years. *Cucurbita* includes five cultivated species: *Cucurbita maxima*, *Cucurbita moschata*, *Cucurbita pepo*, *Cucurbita ficifolia* and *Cucurbita mixta* (Naik *et al.*, 2015). *C. pepo* is the species with the greatest economic value (Paris *et al.*, 2008). The edible portions of *C. pepo*, such as the fruit, flower, leaf and seeds, are rich in sugars, fatty acids, fiber, protein, vitamins and minerals, so they can play a protective role as part of a healthy diet, in cancer prevention and in the treatment of benign prostate hyperplasia (Schmidlin & Kreuter, 2003). However, the few high-quality varieties of *C. pepo* are not enough to satisfy the huge market demand and have limitations in the development of *Cucurbita* breeding programs.

Due to their easy handling, co-dominant inheritance, and highly polymorphic nature, simple sequence repeats (SSRs) are ideal tools for broad applications in basic and applied plant biology (Rabbani *et al.*, 2010; Shah *et al.*, 2015). It has been reported that using SSR flanking sequences, species and genera of plants can be clustered clearly into several genera, such as *Triticum* (Adonina *et al.*, 2005), common bean (Buah *et al.*, 2017), spring barley (Bengtsson *et al.*, 2017), blueberry (Tailor *et al.*, 2017), flax (Choudhary *et al.*, 2017), cucumber (Danin-Poleg *et al.*, 2001; Ritschel *et al.*, 2004; Yang *et al.*, 2016; Dar *et al.*, 2017), melon (Zhu *et al.*, 2016a), and watermelon (Zhu *et al.*, 2016b). Since 48 genotypes of *C.*

pepo, *C. moschata*, and *C. maxima* were classified for the first time based on 27 pairs of SSR markers in *C. pepo* (Stift *et al.*, 2004), a number of SSRs have been developed for *Cucurbita*. *Cucurbita* accessions were assessed and successfully grouped into distinct clusters using SSR markers (Gong *et al.*, 2008; Gong *et al.*, 2012; Murovec, 2015; Sim *et al.*, 2015; Wang *et al.*, 2016a; Zhu *et al.*, 2016b; Kazminska *et al.*, 2017). However, most reports are related to *C. moschata* and *C. maxima*, and research on *C. pepo* is still lacking.

Abundant germplasm resources for *C. pepo* were collected for our research, and the resources with different geographical distributions had varying morphological characteristics. The objective of the present paper was to provide a resource foundation for *C. pepo*, and to analyse the genetic variability and phylogenetic relationships among germplasm resources of *C. pepo* using morphological and molecular markers.

Materials and Methods

Plant materials and experimental design: Sixty-four accessions of *C. pepo* from different geographical regions in China were obtained (Table 1). The seeds of the 64 accessions were germinated at 30°C in the dark for 36 h after being treated with 55°C water for 8h and then transplanted to greenhouse breeding plots at Northeast Agricultural University during the 2015 growing season. Four-leaf stage seedlings from each accession were transferred to experimental plots, and the required irrigation and fertilizer were applied. The experiment was arranged in a randomized complete block design with three replicates.

Morphological characteristics: A total of 45 sets of morphological data of *C. pepo* were recorded, including quantitative and qualitative traits. The quantitative traits included fruit vertical diameter (cm), fruit longitudinal diameter (cm), fruit index, flesh thickness (cm), stalk width (cm), fruit umbilicus diameter (cm), ventricle number, single fruit weight (kg), seed length (cm), seed width (cm), seed thickness (cm), seed kernel weight(g), seed shell weight(g), hundred seed weight(g), seed number per fruit, cotyledon length (cm), cotyledon width (cm), and cotyledon index. The qualitative traits included growth habit, growth vigor, leaf shape, foliage white spotting, number of white spots per leaf, main vine section shape, flower shape, flower size, flower color, floral tube shape, sepal shape, fruit shape, stalk basal enlargement shape, flesh color, skin color, fruit speckle, characteristics of fruit skin, edge and ditch, gourd tumor quantity, gourd skin wax powder, hardness of fruit stem, seed shell, seed color, characteristics of seed beak, seed surface, seed margin, and seed margin color. The morphological traits were divided into 4 groups according to plant development: the cotyledon period, the growing period, the fruit maturation period and the seed harvest period. The morphological characteristics at different stages are listed in Table 2. The quantitative and qualitative morphological data were measured in 10 samples of seeds, fruits and plants per accession.

DNA extraction and polymerase chain reaction: Young leaves from 10 samples from each accession were collected for DNA extraction using the CTAB method (Murray & Thompson, 1980) for SSR marker analysis. A total of 300

SSR markers, including 100 markers from *C. pepo*, 75 markers from www.icugi.org, 100 markers from *C. maxima* (Wang *et al.*, 2016b), and 25 markers from *C. moschata*, were chosen for polymorphism screening. The polymorphic primer sequences used in this study are shown in Table 3. PCR was carried out using 20 μ l samples containing ~40 ng of genomic DNA, 1 μ M of each primer, 400 μ M dNTPs, 1 \times reaction buffer, and 1 U of Taq DNA polymerase. PCR amplifications were performed using the following program: 5min of denaturation at 95°C, 35 cycles of 30 s at 94°C, 30 s at 49°C and 30 s at 72°C and an extension reaction at 72°C for 5 min. The PCR products were analyzed by electrophoresis on 8% polyacrylamide gels. After electrophoresis at 200 V for 1.5 h, the gel was visualized using silver staining.

Data analysis

The quantitative morphological data were calculated in a range from 1 to 10 using the average Euclidean distance to match the cluster analysis format, and the qualitative morphological traits were evaluated according to the methods presented in Table 4. The bands of each SSR marker were scored as presence (1) or absence (0) in the 64 accessions. Clustering was carried out using the unweighted pair group method with arithmetic mean (UPGMA) in the SAHN sub-program, and principal coordinate analyses were performed on the genetic similarity matrix after eigen values and eigenvectors were computed using the Eigen of Ordination program. The statistical analyses were carried out using the NTSYSpc software package, version 2.10e.

Seed margin color	Light=1; similar to seed coat=2; dark=3

Results

Morphological characterization: Most morphological traits of the 64 accessions of *C. pepo* presented large variability, from 6.30% to 70.84% (Tables 5, 6), and 8 traits, including main vine section shape, flower color, sepal shape, stalk basal enlargement shape, characteristics of fruit skin, gourd tumor quantity, gourd skin wax powders, and hardness of the fruit stem, had similar phenotypic features. The average variation coefficient of all varying morphological traits was 34.43%. The largest variation coefficient was 70.84% (for fruit umbilicus diameter), followed by 64.77% (for seed shell weight), and the smallest variation coefficient was 12.72% (for seed width) among the quantitative traits. The highest variation coefficient was 66.77% (for leaf shape), followed by 61.88% (for fruit speckle) and 60.62% (for flesh color), and the lowest variation coefficient was 6.30% (for flower shape seed width) among the qualitative traits. The average variation coefficient of the quantitative traits (32.33%) was slightly lower than the average variation coefficient of the qualitative traits (36.72%).

All morphological traits were divided into 4 groups according to plant development (Table 2). Cotyledon index (CV = 38.71%), fruit umbilicus diameter (CV = 70.84%), leaf shape (CV = 66.77%) and seed shell weight (CV = 64.77%) had the highest variation coefficients during the cotyledon period, fruit maturation period, growing period and seed harvest period, respectively. As

Table 2 shows, the accessions had the richest genetic diversity during the growing period (average CV = 37.88%) among the 4 periods, followed by the fruit maturation period (average CV = 35.69%), the seed harvest period (average CV = 29.15%) and the cotyledon period (average CV = 25.92%).

Based on Shannon's information index, the diversity index of the 64 accessions was calculated (Tables 5, 6). The average Shannon's information index of all varying traits was 1.25, ranging from 0.2% to 4.8%. For qualitative traits, the highest diversity index was observed for seed thickness (with a value of 4.8), and a high diversity index was calculated for seed shell weight, with a value of 2.9. The lowest diversity index was observed for seed width, with a value of 0.2. The diversity index of qualitative traits was the highest for skin color, with a value of 2, followed by fruit shape and fruit speckle (with a value of 1.7), and the lowest value was observed for edge and ditch, with a value of 0.4.

The average diversity index of the quantitative traits (1.49) was much higher than the average diversity index of the qualitative traits (1.07) (Tables 5, 6). Based on a data analysis of the 4 periods, cotyledon index ($I = 1.5$), skin color ($I = 2$), leaf shape ($I = 1.1$) and seed thickness ($I = 4.8$) (Table 2) had the highest diversity indexes during the cotyledon period, fruit maturation period, growing period and seed harvest period, respectively, and the morphological traits of 64 accessions showed high diversity during the seed harvest period (average $I = 1.55$) (Table 2).

Table 5. The basic statistical data of quantitative traits.

Using NTSYS software, the similarity coefficient of all morphological traits among the 64 accessions ranged from 0.19 to 0.76. As shown in Fig. 1, clusters or sub-clusters were clearly defined according to morphological markers. All accessions were grouped into 2 clusters, with a similarity coefficient of 0.253. Five accessions (44, 45, 46, 47 and 48) were included in cluster I, and 59 accessions were included in cluster II. Cluster I was characterized by hull-less seeds, and cluster II was characterized by shell-covered seeds and was composed of 5 sub-clusters with a similarity coefficient of 0.33. Sub-cluster II-I included 1 accession (13) that was semi-

dwarf, with yellow fruit skin, oblong fruit, palmate and pentagonal leaves with mostly white spotting, cylindrical flowers, and a bell-shaped floral tube. Sub-cluster II-II included 2 accessions (95 and 26) that were semi-dwarf, had dark green fruit skin, oval fruits with no wax powder, flat fruit skin with massive speckling, palmate leaves with no white spotting, conical flowers and cylindrical floral tubes. Sub-cluster II-III included 2 accessions (97 and 118) with similar fruit size, tall round fruit with no fruit speckle, heart-shaped leaves with less white spotting, large conical flowers, and open floral tubes. Sub-cluster II-IV included 12 accessions that had

no white leaf spotting, were semi-dwarf or dwarf and had conical flowers and heart-shaped leaves, except for 2 accessions with triangular leaves. Sub-cluster II-V included 42 accessions that were normal dwarfs. In sub-cluster II-V, accessions (36, 51 and 106) with mossy green fruit skin with speckles and less white foliage spotting clustered together. Accessions 10, 17 and 19, which both had tall round fruit without fruit speckle, a large flower size and palmate and pentagonal leaves, clustered together. Accessions 14, 64, 78, 82, 180 and

181 which had yellowish-white seeds with a flat seed beak clustered together. Accessions 7, 12, 24, 39, 43, 63, 66 and 115 clustered together and had similar fruit weights, tall round fruit with light yellow skin, no foliage white spotting, bell-shaped floral tubes. Accessions 5, 18, 30, 31, 40 and 65 with middle to small flowers were clustered together. Accessions 2, 4, 27, 29, 42 and 103 had white colored fruit flesh, yellowish-white seeds with a similar seed size, yellow fruit skin, and white flesh were also clustered together.

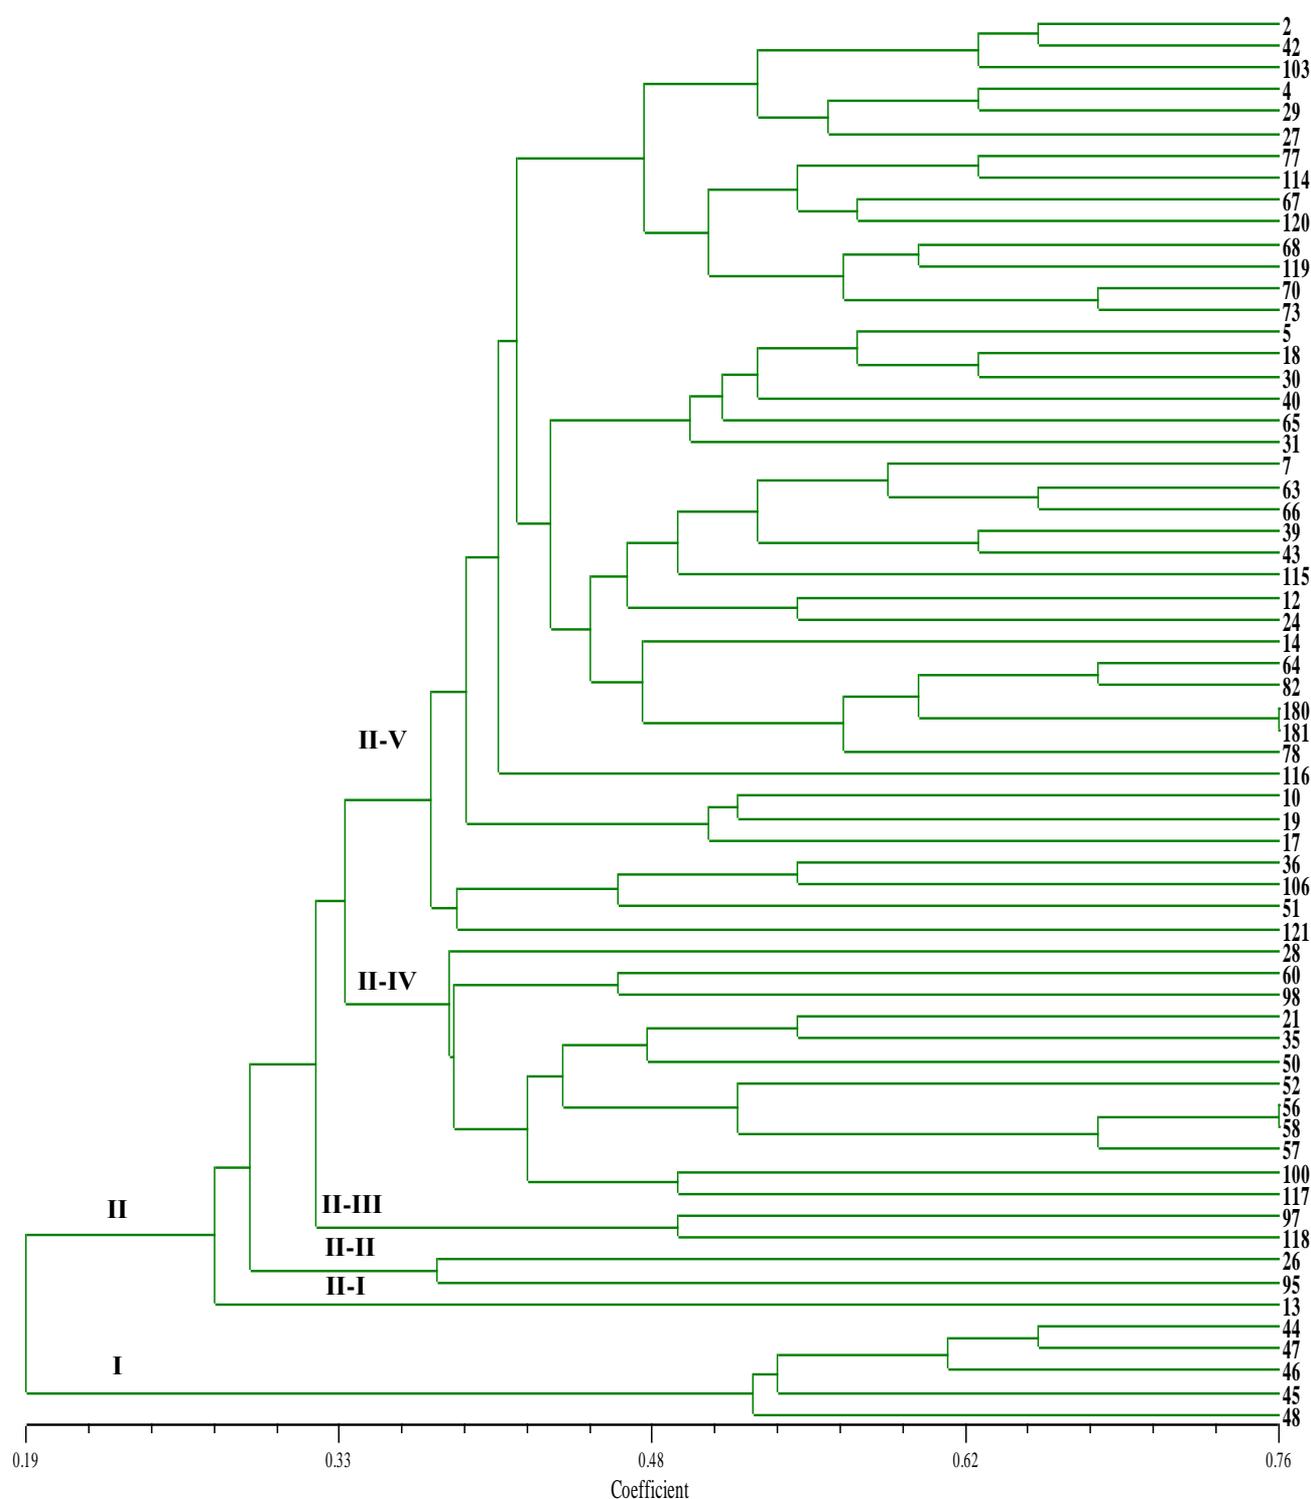

Fig. 1. Cluster analysis of morphological markers. The accessions correspond with the designations listed in Table 1.

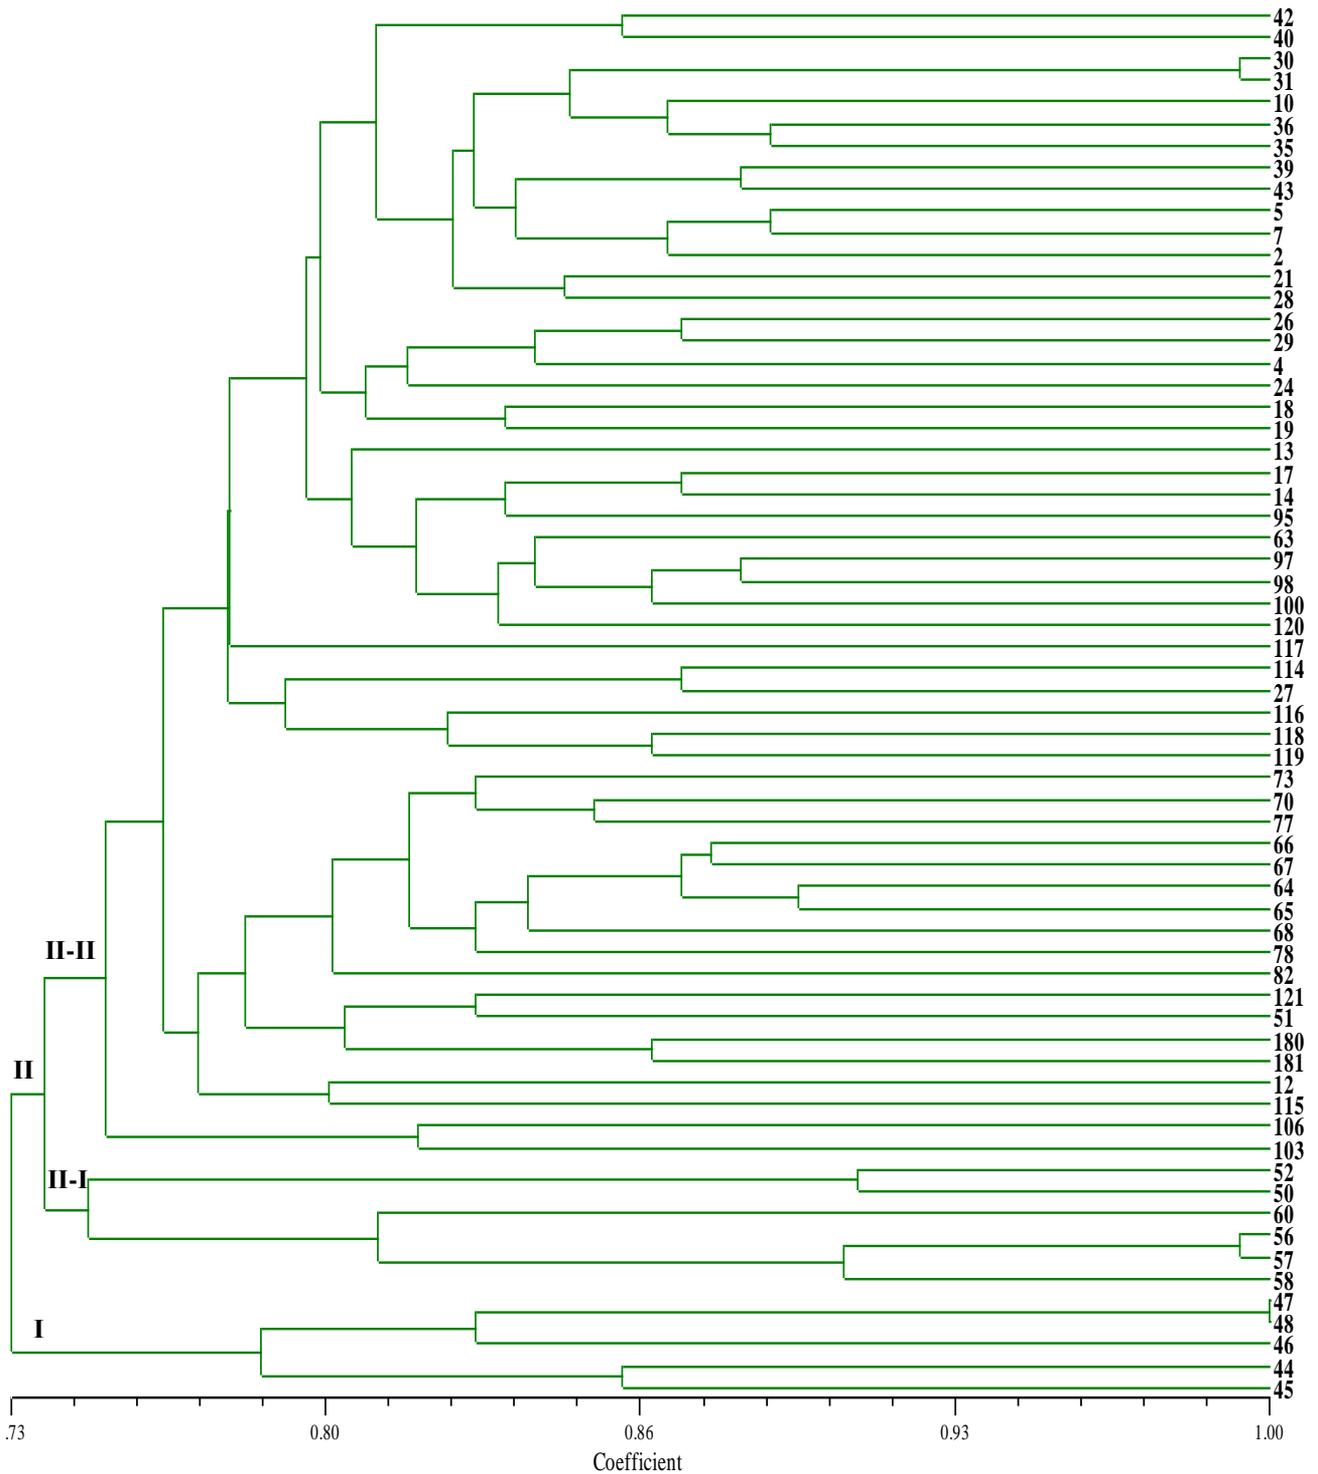

Fig. 3. Dendrogram of resulting from a UPGMA cluster analysis based on SSR markers. The accessions correspond with the designations listed in Table 1.

We further focused on the relationships between the variation coefficient and the diversity index and found no correlation between these factors. The coefficients of variation of fruit umbilicus diameter and seed shell weight were the highest among the morphological traits, but the diversity indexes for these traits were below average. The seed thickness diversity index was the highest, but the variation coefficient for seed thickness was low. Differences between the variation coefficient and the diversity index are caused by many factors. The

coefficient of variation reflects the range of variation and explains the genetic variation by means of deviations from the average, whereas the diversity index describes the frequency distribution and rank difference for a trait. Furthermore, to be amenable to the cluster analysis format, the morphological quantitative data were converted to a range from 1 to 10, which might affect the frequency distribution results. Therefore, these two aspects were both considered to obtain a better understanding of the genetic diversity.

Notes: H': diversity index

The genetic diversity of *Cucurbita* accessions from different geographical origins was identified using molecular markers such as RAPD (Ferriol *et al.*, 2003; Zhao *et al.*, 2017), SSR (Kong *et al.*, 2014; Murovec, 2015; Sim *et al.*, 2015; Kazminska *et al.*, 2017), and HFO-TAG (Harry *et al.*, 2015; Paris *et al.*, 2015), and the results were valuable for further germplasm characterization in different species and for taxonomical identification within the genus *Cucurbita*. In our study, 64 genetic resources were clearly distinguished, and the status of biological classification and genetic relationships among them were identified using 35 highly polymorphic SSR primers. With morphological and molecular markers, 64 accessions were divided into 2 clusters. Cluster I included 5 accessions with hull-less seeds, and cluster II included 59 accessions with shell-covered seeds. The hull-less pumpkins had wider genetic variation than the shell-covered species. The 64 accessions in this study came from various geographical origins in China: 32

from Neimenggu, 15 from Heilongjiang, 10 from Yunnan, 5 from Gansu and 2 from Shanxi. The 10 accessions from Yunnan and the accessions from Neimenggu with dark green fruit were clearly delineated by the SSR analysis in our study. These results were consistent with previous findings by Liu *et al.*, (2013) and Wu *et al.*, (2011), who separated the accessions of *Cucurbita* using molecular markers into sub-clusters that reflected geographical origin.

Based on previous research, 47 accessions of rootstock-used pumpkin were collected, and the genetic diversity and relationships were analyzed with 63 phenotypes and 40 polymorphic SSR markers. Finally, 47 germplasm was divided into 3 groups using SSR primers, which was similar to the results of the morphological study (Li *et al.*, 2014). However, there were also some differences among the relationships of *Cucurbita* accessions revealed by molecular marker and also by morphological marker analysis. The genetic diversity and relationships among *C. moschata* were analyzed by combining morphological characteristics and the molecular markers RAPD (Cai, 2006), SSR (Zheng *et al.*, 2016), SRAP and AFLP (Ferriol *et al.*, 2004). Clustering based on molecular markers had a low correlation with clustering based on morphological characteristics. In our study, Cluster II was divided into 5 sub-clusters with different fruit and leaf shapes based on morphological data, and accessions with similar phenotypic features were grouped together. Cluster II was discriminated into dwarf and normal sub-clusters with SSR markers, and accessions of same origin and similar geographical distribution were clustered together. The results obtained using morphological markers were mildly to moderately correlated with the molecular marker results ($r=0.4647$). There were some differences between the relationships of the 64 *C. pepo* accessions revealed by SSR markers and the relationships revealed by morphological markers. The reasons for this phenomenon are complex. The morphological characteristics correspond to the plant phenotypes which are affected by both innate factors and environmental factors, whereas SSR molecular markers indicate differences in DNA sequence (Rabbani *et al.*, 2010). Moreover, during data collection, morphological marker data can be disturbed by anthropogenic activities or other environmental factors. The SSR marker polymorphisms had low coverage in the complete genomes. Therefore, morphological markers and SSR markers are not interchangeable; rather, they are complementary and together ensure the comprehensiveness and accuracy of analytical results.

Funding: This work was supported by grants from the Heilongjiang Province Foundation for Returnees (LC2016012), the Youth Foundation of Northeast Agricultural University (17QC08).

Conflict of Interest Statement

The authors declare that they have no conflict of interest.

Declaration

The experiments comply with the current laws of the country in which we were performed.

Author contribution statement: Y Wang performed experiment of PCR identification, preparing the manuscript. Y Wang contributed to using data analysis. W Xu contributed to growing plants. C Wang contributed to collecting phenotypic characteristics. C Cui contributed to providing experimental material. S Qu, the corresponding author, oversaw all activities related to the project implementation and manuscript development. All the authors reviewed and approved this manuscript.
